Schumpeterian Growth, Price Rigidities, and the Business Cycles^{*}

Adil Mahroug[†]

Alain Paquet[†]

This version: November 2021

Abstract

Embedding Schumpeterian innovation within a New Keynesian DSGE model matters for the likelihood of innovating when making endogenous decisions about investments in R&D and the path of the technological frontier. This feature brings new challenges at the modeling and simulation stages with implications for the interactions between Schumpeterian innovation and price rigidities, and between business cycle and growth. The interplay of innovation with optimal price setting in the intermediate sector spells out how the technological frontier advances, and how more innovation leads to more price flexibility despite the existence of nominal rigidities.

With a reasonable calibration, key moments and comovements of macroeconomic variables are consistent with their observed counterparts. The Schumpeterian features of the model play a role on the cyclical impacts of various standard shocks and that of a knowledge-spillover shock. Moreover, different combinations of steady-state innovation probability and extent of knowledge spillovers, for the same steady-state growth rate of the economy, have important welfare implications in consumption-equivalent terms.

KEY WORDS: Schumpeterian endogenous growth; Innovation; Business cycles; New Keynesian dynamic stochastic general equilibrium (DSGE) model; nominal price rigidity and flexibility.

1 Introduction

Investing in research and development (*R&D*) leads to innovation that is at the core of a knowledge-based economy and of an endogenous foundation for secular growth, as shown by [Romer \(1986, 1990\)](#), [Lucas \(1988\)](#), [Rebelo \(1991\)](#), and [Aghion and Howitt \(1992\)](#), just to name a few. However, this mechanism is excluded from most dynamic stochastic general equilibrium models as if it is not necessarily relevant for the business cycle. [Ghironi \(2018\)](#) and [Stiglitz \(2018\)](#) challenge the current state of dynamic-stochastic general equilibrium (DSGE) modelling by insisting for the need for more microeconomic foundations, especially when it comes to growth.¹ Indeed, [Comin and Gertler \(2006\)](#) show that *R&D* effects do at business cycle frequencies. [Barlevy \(2007\)](#) and [Fatas \(2000\)](#) both show that investments in innovation are sensitive to monetary policy shocks.

Until recently, relatively few papers had attempted to combine a business cycle model with features of endogenous growth. From the early real business cycle models to the most recent New-Keynesian (NK) macroeconomic models, the usual DSGE model has indeed been constructed around a classical exogenous growth model. Indeed, seminal articles such as [Smets and Wouters \(2007\)](#) and [Justiniano et al. \(2010\)](#) feature calibrated exogenous growth. [Nuño \(2011\)](#) studies a real business cycle model with Schumpeterian growth, using specific functional forms and no nominal rigidity. [Amano et al. \(2012\)](#) add endogenous growth with horizontal innovations in the variety of intermediate goods to study the welfare costs of inflation in an economy with [Taylor \(1980\)](#) staggered price and wage contracts. [Annicchiarico and Rossi \(2013\)](#) look at optimal monetary policy in a NK economy characterized by Calvo staggered prices that embeds endogenous growth induced by knowledge externalities with increasing returns-to-scale.²

¹[Stiglitz \(2018\)](#) argues that “DSGE models are, of course, not really a model of medium- to long-term growth: that is determined by factors like the pace of innovation and the accumulation of human capital on which they provide little insight. To understand the former, for instance, one needs a much more detailed analysis of technological progress, including investments in basic research and the transmission of knowledge across and within firms, than any standard macro-model can provide.” Meanwhile, [Ghironi \(2018\)](#) argues : “If macroeconomics aims to address the dynamics of the last decade and the economic issues that have been central to recent political outcomes, artificial separations between modeling of business cycles and longer-term dynamics must be abandoned, and the same must happen to similarly artificial separations between macroeconomic and trade modeling. [...] So, yes to DSGE, and yes to micro.”

²Other recent work considers longer run issues pertaining to various forms of endogenous growth in economies with different set-up for rigidities. [Annicchiarico et al. \(2011\)](#) consider a NK model with Calvo staggered prices and wages with endogenous growth operating through non-rival access to knowledge to find that the source of the rigidity and the shock persistence on Taylor-type rules matters for the impact of monetary policy on long-run growth. [Annicchiarico and Pelloni \(2014\)](#) examine how nominal rigidities affect uncertainty on long-term growth, when prices and wages are preset with a one-period lag, in a model with labour, as single input, is divided between producing output or *R&D*. [Cozzi et al. \(2017\)](#) show the implication of financial conditions for innovation dynamics in a NK model with Schumpeterian growth with price and wage rigidities arising from specific adjustment costs. Finally, to evaluate the sources of the productivity slowdown following the Great Recession, [Anzoategui et al. \(2017\)](#) estimate a DSGE model with staggered Calvo sluggish adjustments of wages and final-good prices, featuring endogenous growth *via* an expanding variety of intermediate goods resulting from public learning-by-doing in the *R&D* process and an endogenous pace of technology adoption.

Furthermore, there is another important issue that may well matter to understand better the consequences of innovation for efficiency and welfare, namely the interplay of innovation and price flexibility. In an important empirical contribution, [Bils and Klenow \(2004\)](#) had suggested that “another factor potentially related to market competition is the rate at which substitute products are introduced” and that “markets with greater product turnover, as measured by the rate of noncomparable substitutions” could well lead to higher flexibility in prices. Empirically, having reported that, for the 1995-1997 alone, the US Bureau of Labor Statistics had “deemed 46 percent of all [product] substitutions noncomparable”, [Bils and Klenow \(2004\)](#) find indeed that a 1 percent higher noncomparable substitution rate for all goods rises by 1.25 percent the frequency of price changes, even while having accounted for concentration ratio, and wholesale markup.³ We would expect that the arrival of new products has not decreased since the mid-nineties. Indeed, using data from *Adobe Analytics* from January 2014 to September 2017, [Goolsbee and Klenow \(2018\)](#) find that, even when excluding clothings, 44 percent of online sales occurred for products that were inexistent a year earlier.

This motivates us to introduce the distinct ability of new innovating firms with market power to set the optimal price for their good, while facing some likelihood to see their respective price subjected to a rigidity *à la* Calvo for some time in subsequent periods. To our knowledge, this is the first model that explicitly builds the link between price flexibility and innovation, thus allowing the assessment of its possible impact.

Theoretically, attention had to be paid to a meticulous modelling of the interaction between Schumpeterian innovation and price rigidities, as well as to the link between business cycle and growth. The sluggish dynamics of prices have a direct impact on the expected profits of intermediate firms. Beyond providing some justification and microfoundation for market power and monopolistic competition in NK models, the interplay of innovation with optimal price-setting in the intermediate sector both spells out how the technological frontier advances, but also implies that more innovation leads to more price flexibility in a world with nominal rigidities.

Methodologically, the cyclical behaviour of the technological frontier’s growth rate points out the importance of explicitly applying the same cyclical filtering to the trended simulated variables, thus requiring their construction, as well as to their empirical counterparts, as measured. This has ramifications for the interpretation of the cyclical impulse response functions, as well as for the cumulative impact on the levels of macroeconomic variables when accounting for the cyclical response of the average growth rate of the economy. In particular, when considering the impulse response functions of the cyclical components of macroeconomic variables to various shocks, we find that the variables’ dynamics are not invariant to the parameter calibration of steady-state endogenous growth.

³The significant effect is positive when either considering jointly both processed and raw goods, or isolating the impact on processed goods, for which the impact is 2.17 per cent.

A reasonable calibration of our model shows that key moments and comovements for important macroeconomic variables are consistent with their observed counterparts, as well as how the inclusion and treatment of Schumpeterian growth features have non-trivial implications for DSGE models.

Section 2 presents in detail the attributes of our model. We begin with those that are typically encountered in modern New-Keynesian Dynamic Stochastic General Equilibrium (NK-DSGE) set-up, with the necessary adjustments needed to account for the presence of innovating firms. We then direct our attention to the key elements derived from the endogenous Schumpeterian considerations linked to innovations. Section 3 discusses aggregation and the model's general equilibrium, issues dealing with detrending and the steady-state properties of the model, while Section 4 deals with calibration and characterization of the various disturbances that affect our model economy. Section 5 presents and discusses some relevant statistical moments of the cyclical components of the simulated data in comparison with their empirical counterpart. Section 6 displays the impulse response functions implied by the model for the cyclical components of the macroeconomic variables and proceeds with the business cycle analysis implications. Section 7 assesses the impact on welfare associated with different steady-state values for the innovation probability and the extent of knowledge spillover, consistent with the same steady-state growth rate. A summary of our findings and possible extensions conclude with Section 8.

2 The Model

To account jointly for both endogenous growth through creative destruction and business cycles in an extended New Keynesian environment, the proposed model is composed of the following groups of agents: the households, the final good producers, employment agencies, the intermediate good producers, the entrepreneurs/innovators, and a monetary authority. Forward-looking households maximize their expected utility with respect to their sequence of budget constraints, by making optimal decisions regarding their time paths for consumption, labour, utilization of physical capital, private investment, and net bond holdings. Final good producers operate in a perfectly competitive market and use intermediate goods as input. The employment agencies aggregate the households' specialized labour into homogeneous labour used by the intermediate good producers. The latter evolves in a monopolistically competitive setting that allows them to set prices. Operating within each intermediate sector i , entrepreneurs/innovators invest final goods to increase their odds of pushing the technological frontier, so that an intermediate good producer that implements a new technology takes over the incumbent producer in his respective intermediate sector.

We can describe the timing of events within each intermediate sector i as follows

- A time t , the prevailing productivity level $A_{t-1}(i)$ is inherited from the previous period:
 - Step 1: In sector i , a randomly chosen entrepreneur invests $X_t(i)$ in $R\&D$
 - Step 2: The entrepreneur either succeeds or fails. If successful, the innovation pushes the frontier forward to A_t^{max} , that will apply next period
 - Step 3: The incumbent produces $y_t(i)$ with technology $A_{t-1}(i)$ and collects profits

- At time $t + 1$, the successful entrepreneur uses the state-of-the-art technology $A_t(i) = A_t^{max}$ to set a lower price and to eliminate his sector's incumbent:
- Step 1: In sector i , a new entrepreneur invests $X_{t+1}(i)$ in $R\&D$
- ...

Accordingly, an entrepreneur in each sector invests final goods in research and development with the hope of discovering a new technology. The entrepreneur's outcome is binary. He can either succeed or fail. If successful, he reaches the technological frontier $A_t(i)$ which will be used for production next period. At date $t + 1$, the successful entrepreneur eliminates the incumbent in his sector by setting a lower price. He remains in place and collects monopoly profits until he is replaced by another entrepreneur.

Finally, prices and wages face nominal rigidities through contracts *à la* Calvo (1983). Sluggish price adjustments interact directly with the innovation process, as the discounted expected value of investing in $R\&D$ is a function of expected future prices, which matters for the rate of innovation over the business cycles. Monetary policy is set according to a Taylor-type rule, and deviations from thereof. The impacts of a transitory technological shock, a knowledge-spillover shock, and an investment shock are also considered.

We now turn to a detailed presentation of the environment and the problems faced by each type of agents. We first describe the characteristics of the final good producer, the employment agency, and the households' problems. To a large extent, these are very similar to the standard set-up encountered in the modern dynamic stochastic general equilibrium literature. As needed, we introduce features arising from the existence of innovating firms ultimately owned by households. Second, we focus on the specificities brought by Schumpeterian considerations for the innovators and the intermediate good producers, especially given sluggish adjustments in prices. Finally, we address the aggregation issues and we present the monetary authority's policy function.

2.1 A presentation of the common features of a New Keynesian DSGE model

2.1.1 The final good producer

The final consumption good is produced by a representative firm that operates in a perfectly competitive setting and aggregates a continuum of intermediate goods $i \in (0, 1)$ according to the following production function:

$$Y_t = \left(\int_0^1 Y_t(i)^{\frac{\epsilon-1}{\epsilon}} di \right)^{\frac{\epsilon}{\epsilon-1}}, \quad (1)$$

where Y_t is total final output, input $Y_t(i)$ is the good produced by an intermediate level firm i , and $0 \leq \epsilon < \infty$ is the elasticity of substitution between intermediate goods.

The final-good producer takes as given the price of its final output, P_t , and the prices of the intermediate goods, $P_t(i)$. Hence, its profit maximization problem

$$\text{Max}_{Y_t(i)} \Pi_{FG} = P_t Y_t - \int_0^1 P_t(i) Y_t(i) di \quad (2)$$

yields the demand for the i^{th} intermediate good as a negative function of its relative price, namely

$$Y_t(i) = \left(\frac{P_t(i)}{P_t} \right)^{-\epsilon} Y_t. \quad (3)$$

Since economic profits are zero under perfect competition, the nominal value of output is equal to the sum of the nominal value of all intermediate goods i :

$$P_t Y_t = \int_0^1 P_t(i) Y_t(i) di, \quad (4)$$

which, using equation (3), yields the aggregate price index

$$P_t = \left[\int_0^1 P_t(i)^{1-\epsilon} di \right]^{\frac{1}{1-\epsilon}}. \quad (5)$$

2.1.2 The employment agency

A continuum of households possesses different skills and offers specialized labour $L_t(j)$ for $j \in (0, 1)$, that gives them some degree of market power in setting wages. Since intermediate firms use an aggregate form of labour, we can think of a representative employment agency that combines specialized labour according to the following function

$$L_t = \left(\int_0^1 L_t(j)^{\frac{\gamma-1}{\gamma}} dj \right)^{\frac{\gamma}{\gamma-1}}, \quad (6)$$

where $0 \leq \gamma < \infty$ is the elasticity of substitution between each labour type.

Operating in perfect competition, the employment agency maximizes its profits with respect to $L_t(j)$ while taking as given the aggregate wage rate W_t and the prevailing labour compensation specific to each labour type j .

The solution of its optimization problem

$$\text{Max}_{L_t(j)} \Pi_{EA} = W_t L_t - \int_0^1 W_t(j) L_t(j) dj \quad (7)$$

yields the demand for specialized labour j as a negative function of its relative wage rate

$$L_t(j) = \left(\frac{W_t(j)}{W_t} \right)^{-\gamma} L_t. \quad (8)$$

From equation (8), and the competitive equilibrium for the employment agency, the aggregate wage rate is

$$W_t = \left[\int_0^1 W_t(j)^{1-\gamma} dj \right]^{\frac{1}{1-\gamma}} . \quad (9)$$

2.1.3 Households

The Budget Constraint

Each period t , a representative type j household faces the following budget constraint

$$P_t C_t + P_t I_t + P_t a(u_t) \tilde{K}_t + \frac{B_t}{1+R_t} \leq W_t(j) L_t(j) + q_t u_t \tilde{K}_t + B_{t-1} + D_t . \quad (10)$$

As of date t , the household's nominal value for its uses of funds is the sum of its nominal value of consumption in the final good, denoted as $P_t C_t$, of its desired level of investment in capital goods, $P_t I_t$, the resources devoted to adjust the utilization rate of physical capital (if applicable), $P_t a(u_t) \tilde{K}_t$, and its end-of-period net holdings of a one-period discount bond $\frac{B_t}{1+R_t}$, where R_t the nominal interest rate between t and $t+1$.⁴ The aggregate price level P_t applies to consumption, private investment in physical capital, and the adjustment cost of varying capital utilization.

Our set-up allows for a time-varying utilization of the existing stock of physical capital, \tilde{K}_t , provided that the household bears a cost of varying capital utilization u_t . This real cost is captured by a convex function $a(u_t)$ that is increasing in u_t .⁵

Type j household's nominal sources of funds arise from its labour income, i.e. the product of its nominal wage rate $W_t(j)$ and hours worked $L_t(j)$, its nominal payments received from supplying capital services to intermediate firms, from renting some of its existing physical capital, $u_t \tilde{K}_t$, at a gross capital rental rate q_t , the nominal face value of the net discount bond holdings carried from the previous period, and the nominal dividends, D_t , received from its ownership of shares in the intermediate production sector that operates in monopolistic competition.

We, therefore, need to assess the dividends stemming from the economic rent, arising both from monopolistic competition and fruitful investments in $R\&D$. Using aggregate labour and capital, a firm i , belonging to a continuum defined over $i \in (0, 1)$, produces intermediate good i in a monopolistically competitive market, thus generating positive economic profits

$$\Pi_{i,t} = P_t(i) Y_t(i) - w_t L_t(i) - q_t K_t(i) , \quad (11)$$

that are in turn paid as dividends among households. Hence, we can think of each intermediate firm as producing some good i , with a given technology discovered from past $R\&D$ that allowed it to take over sector i .

⁴The net bond holdings may be positive or negative depending on whether the household is either creditor or debtor. Yet, for this closed economy, the aggregate net bond holdings is zero in equilibrium.

⁵Namely, $a(u_t) = a_0 + a_1(u_t - 1) + a_2(u_t - 1)^2$. Hence, when the capital stock is used at full capacity with $u_t = 1$, so that $u_t \tilde{K}_t = K_t$, this real cost function takes a value of zero for $a_0 = 0$, i.e. $a(1) = 0$.

The investment in $R\&D$ has to be accounted for in each period, while being treated as a sunk cost since it is irrelevant whether or not an innovator is successful *ex-post*. Here are two examples to illustrate how to account for the innovation process in the representative household's budget constraint.

Having invested $P_t X_t(i)$ to reach the frontier, a failed innovator generates no profits, as depicted on the timeline of his cash flow in Figure 1.

FIGURE 1: A failed innovator's timeline for cashflows

In this case, the household's budget constraint needs only to include the investment in $R\&D$. The *ex-post* value of engaging in the innovation process is $-P_t X_t(i)$.

By comparison, a successful innovator who invested $P_t X_t(i)$ in $R\&D$, which turns into a successful endeavour that allows to collect monopoly profits $\Pi_{i,t}$ each period, for τ periods, until a new innovation emerges. Figure 2 illustrates the corresponding flow timeline.

FIGURE 2: A successful innovator's timeline for cashflows

Here, the initial investment as well as future profits should be included in the household's budget constraints. It is important, however, to highlight that the profits included in the timeline above do not exclusively result from the innovation process. Indeed, an intermediate firm is already generating profits prior to an innovator taking over. Hence, the profits generated by the intermediate firm after the takeover includes both monopoly and innovation profits.

Accordingly, the overall dividends paid to households are defined as:

$$D_t = \int_0^1 \Pi_{i,t} - P_t X_t(i) \, di . \quad (12)$$

Utility Maximization

As in [Christiano et al. \(2005\)](#), household j maximizes its utility function with respect to the sequence of budget constraints for each period, while taking into account the law of movement of capital. Its preferences for consumption embed habit formation, with an intensity parameter $h > 0$, which generates some additional intrinsic dynamics and persistence on both the demand and supply sides

of the economy following various shocks. The subjective discount factor is $0 < \beta < 1$, the parameter $\theta > 0$ induces disutility of labour, and the parameter $\nu \geq 0$ is the inverse of the Frisch elasticity of labour supply. Furthermore, we assume that the household incurs some cost of adjusting investment $S(\cdot)$, that is a convex function of the investment growth rate.

The representative household must decide how much to consume C_t , while allowing for some habit formation, how many hours $L_t(j)$ to work, how much capacity to use u_t , how much physical capital they want next period \tilde{K}_{t+1} , how much to invest I_t in physical capital, and the size of their net bond holdings B_t by solving the following optimization problem:

$$\text{Max}_{C_{t+s}, L_{t+s}(j), u_{t+s}, \tilde{K}_{t+s+1}, I_{t+s}, B_{t+s}} E_t^j \sum_{s=0}^{\infty} \beta^s \left(\ln(C_{t+s} - h C_{t+s-1}) - \theta \frac{L_{t+s}(j)^{1+\nu}}{1+\nu} \right) \quad (13)$$

subject to

$$P_{t+s} C_{t+s} + P_{t+s} I_{t+s} + P_{t+s} a(u_t) \tilde{K}_{t+s} + \frac{B_{t+s}}{1+i_t} \leq W_{t+s}(j) L_{t+s}(j) + q_{t+s} u_{t+s} \tilde{K}_{t+s} + B_{t+s-1} + D_{t+s} , \quad (14)$$

$$\tilde{K}_{t+s+1} = \mu_{I,t+s} \cdot \left[1 - S\left(\frac{I_{t+s}}{I_{t+s-1}}\right) \right] I_{t+s} + (1-\delta) \tilde{K}_{t+s} , \quad (15)$$

$$\ln \mu_{I,t+s} = \rho_I \ln \mu_{I,t+s-1} + \epsilon_{I,t+s} \quad (16)$$

$$K_{t+s} = u_{t+s} \tilde{K}_{t+s} . \quad (17)$$

where E_t^j is the expectation operator conditioned on known information as of the beginning of period t . The function $S(\cdot)$ is the convex adjustment function cost incurred when varying the level of investment between two periods.⁶ Moreover, an exogenous stochastic investment shock $\mu_{I,t+s}$, that affects the efficiency with which investment is transformed into capital, follows a first-order autoregressive process. Finally, we associate the Lagrange multipliers Λ_t and Φ_t respectively, with the household's budget constraint equation (14), and the investment equation (15) at date t .

In addition, having assumed that a household j possesses some specialized skills underlying some market power over its wage rate, we also assume the existence of wage rigidities modelled with Calvo contract arrangements, with a constant proportion $1 - \xi_w$ being allowed to reoptimize their wage each period. Hence, household j maximizes its expected utility weighed by the probability ξ_w of not being allowed to optimize with respect to wages subject to the labour demand function:

⁶At the calibration stage, we assume it to be defined as $S(I_t/I_{t-1}) = (\kappa/2) \cdot (I_t/I_{t-1} - g_t)^2$. Hence, the investment adjustment cost is defined in relation with departure of physical investment growth from its steady-state trend growth, i.e. that of the technological frontier in the steady state.

$$\text{Max}_{W_{t+s}(j)} E_t^j \left(\sum_{s=0}^{\infty} \xi_w^s \beta^s \left(-\theta \frac{L_{t+s}(j)^{1+\nu}}{1+\nu} \right) + \Lambda_{t+s} W_{t+s}(j) L_{t+s}(j) \right) \quad (18)$$

subject to

$$L_{t+s}(j) = \left(\frac{W_t(j)}{W_{t+s}} \right)^\gamma L_{t+s} . \quad (19)$$

Accordingly, the optimal reset wage is obtained from

$$W_t^*(j)^{-\gamma\nu-1} = \frac{\gamma-1}{\theta\gamma} \frac{\sum_{s=0}^{\infty} \xi_w^s \beta^s \Lambda_{t+s} W_{t+s}^\gamma L_{t+s}}{\sum_{s=0}^{\infty} \xi_w^s \beta^s W_{t+s}^{\gamma(1+\nu)} L_{t+s}^{1+\nu}} . \quad (20)$$

Exploiting the relevant recursions built in the summation, which, in turn, will be useful for subsequent numeric simulation, equation (20) can be rewritten as

$$W_t^*(j)^{-\gamma\nu-1} = \frac{\gamma-1}{\theta\gamma} \frac{Aux_{bc,t}}{Aux_{dis,t}} , \quad (21)$$

where, we define auxiliary variables associated respectively with the household's budget constraint in the numerator, $Aux_{bc,t}$, and the disutility of labour in the denominator, $Aux_{dis,t}$, i.e.

$$Aux_{bc,t} = \Lambda_t W_t^\gamma L_t + \xi_w \beta Aux_{bc,t+1} , \quad (22)$$

and

$$Aux_{dis,t} = \Lambda_t W_t^{\gamma(1+\nu)} L_t^{1+\nu} + \xi_w \beta Aux_{dis,t+1} . \quad (23)$$

2.2 The Schumpeterian add-ons in a New-Keynesian DSGE model and their implications

As it is commonly used in the academic literature, and even in policy documents, the concept of innovation is somewhat broad. Not all innovations amount to paradigm shifting, as ground-breaking discoveries, such as the steam engine, seldom occur. Hence, by innovation, we mean anything that pushes the technological frontier forward, even incrementally so. As such, incremental innovations can be understood as improvement in either the intermediate good itself, or in its production process. In our model, both innovations push up the technological frontier and push down the marginal cost of production.⁷

⁷As pointed out by Kirschenbaum (2018), “invention and innovation are also about revision and refinement, a gradual process of shaping, adaptation, and perhaps, elusively, perfection. Invention, in other words, is a lot like word processing itself, which allows us to continuously edit our ideas, cutting and pasting, inserting and deleting until we get what we're working on just where we want it”.

Building on [Aghion and Howitt \(1992\)](#) and [Nuño \(2011\)](#), our Schumpeterian growth paradigm assumes that an innovation may arise from investing in $R\&D$ in period $t-1$ and push the technology level at A_{t-1}^{max} for an intermediate firm operating at date t with an endogenous probability n_{t-1} , making it an advanced firm. Otherwise, there is a $1 - n_{t-1}$ probability that an intermediate firm is lagging, while still using an older technology level.

However, the existence of price stickiness adds an additional level of complexity that is absent in typical Schumpeterian growth models, as well as in recent business cycle models with Schumpeterian features. Namely, since the monopolistic rent depends on the expected prices that the firm may or may not be allowed to reset, the value of the firm and, therefore, the investment in $R\&D$ is also a function of the expected paths for prices.

While implementing an innovation, we assume that an intermediate firm is allowed to set the optimal price right away. However, in subsequent periods, barring some new innovation, the same intermediate firm is stuck with a more or less older technology, and there is a probability that its price remains sticky for some time. Indeed, if it is not innovating, the lagging firms are in a Calvo-type environment as in standard New Keynesian models.

Hence, three categories of intermediate firms coexist: advanced firms which reset their price, lagging firms allowed to reoptimize their price, and lagging firms with previously set prices.

2.2.1 The optimal reset price

Operating in a monopolistically competitive market, intermediate firms hold market power from both their specialization and the technology used in production. In itself, it is worth noticing that the mechanics of innovation being considered also brings some support and microfoundations to the monopolistic competition *de facto* introduced in the usual New Keynesian models. In the intermediate sector, each period, some firms have not been supplanted and operate with a lagging technology, while others are kicked out as they are being replaced by firms with an advanced technology. For firms operating with a lagging technology, prices are fixed through Calvo contracts. Amongst them, there is a share, given by $1 - \xi_p$, that are allowed to reset their price. However, in the period they introduce an innovative technology, advanced firms are allowed to set the optimal price. When allowed, all firms set the price of their respective intermediate good to maximize their expected profits.

Hence, given an initial level of technological advancement $A_t(i)$, an intermediate firm seeks to minimize their cost:

$$\text{Min}_{K_t(i), L_t(i)} W_t L_t(i) + q_t K_t(i) \quad (25)$$

subject to

$$Y_t(i) = \mu_{Z,t} A_t(i)^{1-\alpha} K_t(i)^\alpha L_t(i)^{1-\alpha} , \quad (26)$$

with $\alpha \in (0, 1)$, where

$$\ln \mu_{Z,t} = \rho_Z \ln \mu_{Z,t-1} + \epsilon_{Z,t} . \quad (27)$$

Hence, regardless of their individual level of technological advancement, all intermediate firms' productions are subjected to a common transitory technological shock, that follows a first-order autoregressive process.

Accordingly, as all intermediate firms are symmetrical, they all employ the same optimal capital-labour ratio, i.e.

$$\frac{K_t}{L_t} = \frac{\alpha}{1-\alpha} \frac{W_t}{q_t} , \quad (28)$$

and the nominal marginal cost of producing an additional unit of intermediate good is given by

$$MC_t(i) = A_t(i)^{\alpha-1} \Omega_t , \quad (29)$$

where Ω_t is the portion of marginal costs that is not directly dependent on technology, i.e.

$$\Omega_t = \frac{q_t^\alpha W_t^{1-\alpha}}{\alpha^\alpha (1-\alpha)^{1-\alpha}} . \quad (30)$$

This shows that an improvement in technology translates into a reduction in a firm's marginal cost.

In traditional New-Keynesian models, all firms operate at the same level of technological advancement, so that, when possible, all firms set the same optimal reset price. In contrast, in our set-up, since the optimal reset price depends on the technology with an infinite number of intermediate firms, there is an infinite number of coexisting technologies. Accordingly, there is an infinite number of reset prices because the marginal cost is a function of the technology level.

Consequently, given their respective marginal cost, intermediate firms maximize their profits with respect to their price $P_t(i)$:

$$\begin{aligned} \max_{P_t(i)} E_t \left\{ \left(P_t(i) - MC_t(i) \right) Y_t(i) \right. \\ \left. + \sum_{s=1}^{\infty} \xi_p^s \beta^s \frac{\Lambda_{t+s}}{\Lambda_t} \left[\prod_{q=1}^s (1 - n_{t+q-1}) \left(P_t(i) - MC_{t+s}(i) \right) Y_{t+s}(i) \right] \right\} \end{aligned}$$

subject to

$$Y_{t+s}(i) = \left(\frac{P_t(i)}{P_{t+s}} \right)^{-\epsilon} Y_{t+s} . \quad (31)$$

Notice that the initial level of technology is known and can differ between firms.

Thus, it can be shown that the optimal reset price is a function of initial technology $A_t(i)$, and of a factor F_t that is not directly dependent on technology:

$$P_t^*(i) = A_t(i)^{\alpha-1} F_t , \quad (32)$$

where

$$F_t = \frac{\epsilon}{\epsilon - 1} \frac{Aux_{cost,t}}{Aux_{rev,t}} , \quad (33)$$

$$Aux_{rev,t} = P_t^\epsilon Y_t + \xi_p \beta \frac{\Lambda_{t+1}}{\Lambda_t} (1 - n_t) Aux_{rev,t+1} , \quad (34)$$

and

$$Aux_{cost,t} = \Omega_t P_t^\epsilon Y_t + \xi_p \beta \frac{\Lambda_{t+1}}{\Lambda_t} (1 - n_t) Aux_{cost,t+1} . \quad (35)$$

2.2.2 The innovation process

R&D activities are conducted by entrepreneurs/innovators. If these lead to an innovation, its implementation by an intermediate good producer conveys some additional market power from producing an improved version of the intermediate good, as it reaches the new technological frontier. Hence, the innovation process unfolds within the intermediate sector to push the technological frontier outward.

An entrepreneur/innovator invests some amount of final goods to raise the probability of innovating. Outside researchers or a new successful innovator supplants or “leapfrogs” an incumbent entrepreneur.⁸ This prospect is, however, uncertain as the probability to innovate is n_t , and that of not discovering is $1 - n_t$. Yet, n_t is endogenous as it is linked to the intensity of *R&D* effort $\frac{X_t}{\zeta A_t^{max}}$, where X_t is the real amount of final goods invested in *R&D*, A_t^{max} is the targeted technology level, or frontier, that will be used in date $t+1$ production, and $\zeta > 1$ is a scaling factor that can be derived from an innovation. In particular, when striving for a larger value of A_t^{max} , a higher degree of complexity associated with further technological progress is reflected by the smaller level of intensity of *R&D* effort obtained from a given amount of resources X_t . Finally, we consider the following innovation production function that exhibits diminishing marginal returns, with $\eta > 0$:

⁸In our model, we therefore abstract from step-by-step technological progress, that would imply both Schumpeterian and escape-competition effects. This can also be justified by assuming that, from engaging in *R&D*, it is prohibitively costly to develop a perfectly substitutable technology that can be used to produce a cheap and faked copy of an existing intermediate good, i.e. a knockoff.

$$n_t = \left(\frac{X_t}{\zeta A_t^{max}} \right)^{1/(1+\eta)} . \quad (36)$$

Furthermore, the gross growth rate of the technological frontier A_t^{max} is dictated by the probability of innovation times a spillover factor, which is subject to some first-order autoregressive stochastic component. This defines a proportional increase in productivity resulting from an innovation.⁹

Namely,

$$A_t^{max} = g_t^{max} \cdot A_{t-1}^{max} , \quad (37)$$

$$g_t^{max} = 1 + \varphi_t n_{t-1} , \quad (38)$$

where

$$\ln \varphi_t = \ln \varphi + \rho_\varphi \ln \varphi_{t-1} + \epsilon_{\varphi,t} . \quad (39)$$

The introduction of a stochastic spillover shock on φ_t can account for unpredictable variations and other heterogeneities in the transmission of knowledge and/or abilities to capitalize on new innovations to push the technological frontier further. Hence, a knowledge spillover is the positive externality derived from an innovation, since it permanently pushes the technological frontier forward.¹⁰ The higher the value of φ_t , the greater is the extent of technology spillover, which, in turn, induces a larger technological jump of the frontier.

To choose the amount of final good to be invested in *R&D* that maximizes expected discounted profits, the entrepreneur in sector *i* faces the following constrained optimization problem

$$\text{Max}_{X_t} \beta \frac{\Lambda_{t+1}}{\Lambda_t} n_t E_t V_{t+1}(A_t^{max}) - P_t X_t \quad (40)$$

⁹While the steady state growth rate of the frontier is constant, the frontier itself could follow different paths. Indeed, a small deviation of the growth rate, caused by the stochastic nature of the model, could put the evolution of technology on different trajectories.

¹⁰Baldwin et al. (2005) have shown, both theoretically and empirically, how knowledge spillovers generated by multinational corporations and foreign direct investments endogenously enhance growth. It is natural to argue that a similar effect can span across firms within an industry, as well as across industries to some extent. For instance, we can think of spillovers from the diffusion in information and communication technologies. In particular, Filippetti et al. (2011) find that successful international competition is fostered by innovation, that is itself reinforced by “exposure to alternative business and innovations contexts.” Moreover, based on industry level data for 15 OECD countries, Saia et al. (2015) recently showed the significance of knowledge spillovers for an economy’s effectiveness to learn from the technological frontier and to increase productivity. An economy’s spillovers stem from “its degree of international connectedness, ability to allocate skills efficiently and investments in knowledge-based capital, including managerial capital and *R&D*.”

subject to equation (36), where $E_t V_{t+1}(A_t^{max})$ is the expected discounted value of future profits contingent on the entrepreneur remaining at the helm of the monopoly. If successful, the innovator will collect monopoly profits as long as no further innovation occurs in his sector.¹¹

For convenience and in a way that is compatible with complete markets, we assume that entrepreneurs invest in a diversified form of $R\&D$. Strictly speaking, this is as if an entrepreneur, provided one is successful, does not know in which sector, one may end up. This implies that all entrepreneurs will invest the same amount of final good in $R\&D$. Consequently, if an innovation occurs, the technology jumps to the frontier and the expected value of the intermediate firm will be the same regardless of the intermediate sector. In accordance with the problem in equation (40), optimal real investment in $R\&D$ is given by

$$X_t = \beta \frac{n_t}{1 + \eta} \frac{\Lambda_{t+1}}{\Lambda_t} \frac{E_t V_{t+1}(A_t^{max})}{P_t} . \quad (41)$$

To solve for X_t , we still need to write explicitly the expected value of the firm to the entrepreneur. This is more challenging than it may look at first, as all possible paths for that prices are expected to follow.

The first hurdle is to ensure that the assessment of future profits follows the correct technological path. For instance, an innovator's technology may reach the frontier A_t^{max} in $t + 1$, and remains at that level, say until $t + 3$, as it is supplanted by an advanced firm, with a newer technology and a lower marginal cost. In this situation, from then on, the following expected profits no longer matter for investing in innovation since it is now out of business.

The second difficulty springs from price rigidities that play a crucial role in determining future profits because they condition both the profit margin and the conditional demand for that specific intermediate good. Innovative intermediate firms that jump to the frontier are automatically allowed to reoptimize. Non-innovating ones may be selected for reoptimization using Calvo contracts, with a probability $1 - \xi_p$. Because we assume that investments in $R\&D$ are diversified by the entrepreneurs/innovators, even though an entrepreneur ignores *ex-ante* the sector in which he will be innovating, he can evaluate the discounted expected profits from a potential discovery.

¹¹In our model, with a steady-state probability of innovation n_{ss} , the expected life span of an intermediate firm at steady-state is $1/n_{ss}$.

To reckon the value of an innovation-implementing intermediate firm, let us consider an entrepreneur/innovator who, at date t , ponders how much to invest in $R\&D$ while seeking some returns from date $t + 1$ onward. This evaluation must take into account different possible outcomes that reflect the probability of remaining at the helm of the monopoly, the appropriate stochastic discount factors, as well as the probability that price reoptimization occurs under Calvo contracts. This is why, we have to consider all possible contingencies that could deliver some return from innovating.¹²

First, let us think about the case of a new monopolist taking over as of date $t + 1$ and setting the optimal price for its intermediate good i . As he has innovated, his prevailing specific technology reaches the new technological frontier, so that $A_t(i) = A_t^{max}$. He faces each period the probability ξ_p of not being allowed to optimize its price afterwards, so that, for the contingency path that price reoptimization never occurs, his expected discounted stream of profits would be given by

$$\Psi_{1t+1}(i) = \sum_{s=1}^{\infty} \xi_p^{s-1} \beta^{s-1} \frac{\Lambda_{t+s}}{\Lambda_{t+1}} \left[P_{t+1}^*(i) \pi_{p,t,t+s} - MC_{t+s}(i) \right] Y_{t+s}(i) \prod_{q=2}^s (1 - n_{t+q-1}) , \quad (42)$$

where $\prod_{q=2}^s (1 - n_{t+q-1})$, is the probability of not being displaced out of business at date $t + s$. The flows of revenues and costs are discounted from date $t + 1$, as the nested sum is discounted up to the beginning of the initial cash flow pertaining to this stream, and weighted by the probability of remaining at the helm of the monopoly for all periods in the future. In particular, date $t + 1$ cash flow has a unit probability, i.e. $\prod_{q=2}^1 (1 - n_{t+q-1}) = 1$, as we consider a successful innovation driving the production of intermediate good i that is sold at its optimal price. Moreover, if an intermediate firm producing good i is replaced following the implementation of a new innovation in this sector at some future date T , then no additional profits will accrue from then on from the older technology.

As long as it has not been supplanted, this monopolist will be operating under technology A_t^{max} . Hence, his marginal cost of production evolves according to

$$MC_{t+s}(i) = A_t^{max(\alpha-1)} \Omega_{t+s} , \quad (43)$$

while his optimal price is set to

$$P_{t+1}^*(i) = A_t^{max(\alpha-1)} F_{t+1} , \quad (44)$$

and the expected demand for his good follows a path defined by

$$Y_{t+s}(i) = \left(\frac{P_{t+1}^*(i)}{P_{t+s}} \right)^{-\epsilon} Y_{t+s} . \quad (45)$$

¹²Notice that if the monopolist is supplanted at a future date by a competitor's adoption of an innovation, expected profits are to become zero from that date forward, with no bearing on the current expected discounted flow of profits for date t investing entrepreneur.

Using equations (43), (44), and (45), equation (42) can be rewritten as

$$\begin{aligned} \Psi_{1t+1}(i) = & A_t^{max(\alpha-1)(1-\epsilon)} \left\{ F_{t+1}^{(1-\epsilon)} \sum_{s=1}^{\infty} \xi_p^{s-1} \beta^{s-1} \frac{\Lambda_{t+s}}{\Lambda_{t+1}} P_{t+s}^{\epsilon} Y_{t+s} \prod_{q=2}^s (1 - n_{t+q-1}) \right. \\ & \left. - F_{t+1}^{-\epsilon} \sum_{s=1}^{\infty} \xi_p^{s-1} \beta^{s-1} \frac{\Lambda_{t+s}}{\Lambda_{t+1}} P_{t+s}^{\epsilon} \Omega_{t+s} Y_{t+s} \prod_{q=2}^s (1 - n_{t+q-1}) \right\}. \end{aligned} \quad (46)$$

Making use of equations (34) and (35), but as of $t + 1$, we therefore have

$$\Psi_{1t+1}(i) = A_t^{max(\alpha-1)(1-\epsilon)} \left(F_{t+1}^{(1-\epsilon)} Aux_{rev,t+1} - F_{t+1}^{-\epsilon} Aux_{cost,t+1} \right), \quad (47)$$

with auxiliary variables associated respectively with the firm's revenues in the first term, $Aux_{rev,t}$, and costs in the second term, $Aux_{cost,t}$, i.e.

$$Aux_{rev,t+1} = P_{t+1}^{\epsilon} Y_{t+1} + \xi_p \beta \frac{\Lambda_{t+2}}{\Lambda_{t+1}} (1 - n_{t+1}) Aux_{rev,t+2}, \quad (48)$$

and

$$Aux_{cost,t+1} = \Omega_{t+1} P_{t+1}^{\epsilon} Y_{t+1} + \xi_p \beta \frac{\Lambda_{t+2}}{\Lambda_{t+1}} (1 - n_{t+1}) Aux_{cost,t+2}. \quad (49)$$

Second, let us turn to all the other possible cases of a new monopolist taking over as of date $t + 1$ and setting the optimal price for its intermediate good i at some future date $t + l$ with some probability $1 - \xi_p$, yet followed by the contingency path that price reoptimization does not occur afterwards, as there is a probability ξ_p each period of no reoptimization, even if the monopolist remains in operation. Summing over all contingent paths, with the proper probabilistic weights, the relevant discounted stream of profits for all these contingent paths is given by

$$\begin{aligned} \Psi_{2t+1}(i) = & A_t^{max(\alpha-1)(1-\epsilon)} \left\{ \sum_{l=2}^{\infty} (1 - \xi_p) \beta^l \frac{\Lambda_{t+l}}{\Lambda_{t+1}} \prod_{q=2}^{l-1} (1 - n_{t+q-1}) \right. \\ & \cdot \left[F_{t+l}^{1-\epsilon} \sum_{s=l}^{\infty} \xi_p^{s-1} \beta^{s-1} \frac{\Lambda_{t+s}}{\Lambda_{t+l}} P_{t+s}^{\epsilon} Y_{t+s} \prod_{q=l}^s (1 - n_{t+q-1}) \right. \\ & \left. \left. - F_{t+l}^{-\epsilon} \sum_{s=l}^{\infty} \xi_p^{s-1} \beta^{s-1} \frac{\Lambda_{t+s}}{\Lambda_{t+l}} P_{t+s}^{\epsilon} \Omega_{t+s} Y_{t+s} \prod_{q=l}^s (1 - n_{t+q-1}) \right] \right\}. \end{aligned} \quad (50)$$

Furthermore, updating equations (48) and (49) to date $t + l$, equation (50) can be rewritten as

$$\Psi_{2t+1}(i) = A_t^{max(\alpha-1)(1-\epsilon)} \quad (51)$$

$$\cdot \left\{ \sum_{l=2}^{\infty} (1 - \xi_p) \beta^l \frac{\Lambda_{t+l}}{\Lambda_{t+1}} \prod_{q=2}^{l-1} (1 - n_{t+q-1}) \left(F_{t+l}^{(1-\epsilon)} Aux_{rev,t+l} - F_{t+l}^{-\epsilon} Aux_{cost,t+l} \right) \right\} .$$

In an analogous manner as before, making use of the recursion built in the summations above and defining an auxiliary variable, $Aux_{rem,t+l}$, associated with the remainder of the expected discounted profits equation (51) can also be displayed as

$$\Psi_{2t+1}(i) = A_t^{max(\alpha-1)(1-\epsilon)} \cdot Aux_{rem,t+2} , \quad (52)$$

where

$$\begin{aligned} Aux_{rem,t+2} = (1 - \xi_p) \beta^2 \frac{\Lambda_{t+2}}{\Lambda_{t+1}} & \left(F_{t+2}^{(1-\epsilon)} Aux_{rev,t+2} - F_{t+2}^{-\epsilon} Aux_{cost,t+2} \right) \\ & + \beta (1 - n_{t+2}) Aux_{rem,t+3} . \end{aligned} \quad (53)$$

Consequently, the expected value of the intermediate firm to a successful innovator is

$$E_t V_{t+1} = \Psi_{1t+1}(i) + \Psi_{2t+1}(i) \quad (54)$$

or, namely,

$$E_t V_{t+1} = A_t^{max(\alpha-1)(1-\epsilon)} \cdot \left(F_{t+1}^{1-\epsilon} Aux_{rev,t+1} - F_{t+1}^{-\epsilon} Aux_{cost,t+1} + Aux_{rem,t+2} \right) . \quad (55)$$

Hence, the expected value of an intermediate firm for a successful entrepreneur/innovator is determined by the newly reached technological frontier through $A_t^{max(\alpha-1)(1-\epsilon)}$, the contribution from profits arising from being able to set the optimal price for good i as of period $t + 1$ through $F_{t+1}^{1-\epsilon} Aux_{rev,t+1} - F_{t+1}^{-\epsilon} Aux_{cost,t+1}$, and the contribution to profits resulting from a later date optimal price setting with what will have become an older technology through $Aux_{rem,t+2}$.

2.3 The specification of monetary policy

The central bank's policy function is modelled as a Taylor-type reaction function, as it sets the nominal interest rate according to the following equation:

$$\frac{1 + R_t}{1 + R} = \left(\frac{1 + R_{t-1}}{1 + R} \right)^{\rho_R} \left[\left(\frac{\pi_t}{\pi} \right)^{\alpha_\pi} \left(\frac{Y_t}{Y_{t-1}} g^{-1} \right)^{\alpha_y} \right]^{1-\rho_R} \mu_{M,t} , \quad (56)$$

where

$$\ln \mu_{M,t} = \rho_M \ln \mu_{M,t-1} + \epsilon_{M,t} . \quad (57)$$

The ρ_R parameter represents the degree of smoothing of interest rate changes, as the monetary authority seeks to avoid too large changes with respect to its one-period-lag value, R_{t-1} , and adjusts it somewhat gradually, with weight $1 - \rho_R$, following demand and technology shocks. The parameters α_π and α_y are the monetary authority's weights attached to deviations from its inflation target, π , and its output growth target, g . The latter is defined as the growth rate of the average technology level in steady state. Finally, $\mu_{M,t}$ is an exogenous and stochastic component of monetary policy representing deviations from the Taylor-type rule, that follows a stationary first-order autoregressive process.

3 The Aggregate Economy

We now turn to the aggregation of the key economic variables and the equilibrium conditions.

3.1 The aggregate price level

From equation (5), the overall economy's aggregate price level can be inferred by weighting and combining each of the respective prices for the three categories of coexisting firms

$$P_t^{1-\epsilon} = \xi_p (1 - n_{t-1}) (P_{t-1})^{1-\epsilon} + (1 - \xi_p) \int_{n_{t-1}}^1 P_t^*(i)^{1-\epsilon} di + \int_0^{n_{t-1}} P_t^*(i)^{1-\epsilon} di . \quad (58)$$

The first term above corresponds to firms operating some older technologies that are not allowed to reset their prices. The second term is associated to firms using older technologies that can reset their optimal price. Finally, the last group is that of new monopolists adopting the most recent technology and accordingly setting its intermediate-good optimal price.¹³

In a conventional New Keynesian model in which long-term growth is exogenous, the price index includes both prices indexed to inflation and optimal reset prices. However, in an endogenous growth environment, we have to consider separately and explicitly, both reoptimizing-firms types: those that have innovated and those that have not. Innovating firms all set the same optimal reset price, as they are automatically allowed to reoptimize. Lagging firms set different optimal reset prices according to their respective level of technological advancement. The difference between these two indices, as captured by the third term on the right-hand side of equation (58), is related to what [Aghion et al. \(2018\)](#) identify as missing growth. As they point out, a measurement error in inflation stems from leaving the impact of innovative goods out. In turn, this error has consequential implications for the effective real output growth rates. Since real output growth is obtained by subtracting inflation from nominal output growth, an overestimation of inflation leads to an underestimation of output growth. This is likely to have implications for monetary policy, as well as for the design of subsidization and tax-credit policies conducive to *R&D*, that could be considered in future work.

Exploiting the implicit recursion embedded in equation (58), we can show that

¹³The implied dynamics of this aggregate price level involves a corresponding New Keynesian Phillips curve that is discussed in a subsequent subsection.

$$P_t^{1-\epsilon} = \xi_p (1 - n_{t-1}) (P_{t-1})^{1-\epsilon} + (1 - \xi_p)(1 - n_{t-1}) F_t^{1-\epsilon} Aux_{oldtech,t-1} + n_{t-1} A_{t-1}^{max(\alpha-1)(\epsilon-1)} F_t^{1-\epsilon} \quad (59)$$

where

$$Aux_{oldtech,t-1} = n_{t-2} A_{t-2}^{max(\alpha-1)(1-\epsilon)} + (1 - n_{t-2}) Aux_{oldtech,t-2} . \quad (60)$$

The auxiliary variable, denoted by $Aux_{oldtech,t-1}$, is itself a weighted average of the older technology levels prevailing as of date $t - 1$.

3.2 The aggregate wage rate

From the aggregate wage index, defined by equation (9), the overall economy's wage index can be inferred from weighting the respective wages for the workers that cannot reset their wage optimally, and those that are allowed to reset to the optimal wage, i.e.

$$W_t^{1-\gamma} = \xi_w (W_{t-1})^{1-\gamma} + (1 - \xi_w) W_t^{*1-\gamma} . \quad (61)$$

3.3 Aggregate output

The aggregation of output needs to account for the fact that many intermediate firms coexist with different technology levels and, hence, specific output levels.

From equations (3) and (26), considering that the optimal capital-labour ratio is identical for all firms, and integrating over all the firms on the $[0, 1]$ continuum, we can show that

$$\mu_{Z,t} K_t^\alpha L_t^{1-\alpha} = P_t^\epsilon Y_t \int_0^1 A_t(i)^{\alpha-1} P_t(i)^{-\epsilon} di . \quad (62)$$

Since three classes of situations arise, the integral in equation (62) can be accordingly evaluated over three subintervals:

$$\mu_{Z,t} K_t^\alpha L_t^{1-\alpha} = P_t^\epsilon Y_t \cdot \left[\int_0^{\xi_p(1-n_{t-1})} A_t(i)^{\alpha-1} P_t(i)^{-\epsilon} di + \int_{\xi_p(1-n_{t-1})}^{1-n_{t-1}} A_t(i)^{\alpha-1} P_t^*(i)^{-\epsilon} di + \int_{1-n_{t-1}}^1 A_t(i)^{\alpha-1} P_t^*(i)^{-\epsilon} di \right] . \quad (63)$$

The first and second intervals include old-technology-running firms that are respectively non resetting, and optimally resetting their price at $P_t^*(i)$. The last one covers the innovating firms with optimal price setting at $P_t^*(i)$. Using equation (32), the above equation becomes

$$\begin{aligned} \mu_{Z,t} K_t^\alpha L_t^{1-\alpha} = P_t^\epsilon Y_t \cdot & \left[(P_{t-1})^{-\epsilon} \int_0^{\xi_p(1-n_{t-1})} A_t(i)^{\alpha-1} di \right. \\ & + F_t^{-\epsilon} \int_{\xi_p(1-n_{t-1})}^{1-n_{t-1}} A_t(i)^{(1-\epsilon)(\alpha-1)} di + F_t^{-\epsilon} \int_{1-n_{t-1}}^1 A_t(i)^{(1-\epsilon)(\alpha-1)} di \left. \right] . \end{aligned} \quad (64)$$

Then, since the firms involved within the first and second integrals operate older technologies, as they do not innovate, the distribution of technologies in these sectors is identical to that of the entire economy as it was one period before. Accordingly, we can define auxiliary variables that can be used to evaluate the relevant integrals by exploiting corresponding recursions. Namely, we can show that:

$$\begin{aligned} \int_0^{\xi_p(1-n_{t-1})} A_t(i)^{(\alpha-1)} di &= Aux_{oldtechnonreset,t-1} \\ &= \xi_p(1-n_{t-1}) A_{t-2}^{max(\alpha-1)} + (1-n_{t-2}) Aux_{oldtechnonreset,t-2} , \end{aligned} \quad (65)$$

and

$$\int_{\xi_p(1-n_{t-1})}^{1-n_{t-1}} A_t(i)^{(1-\epsilon)(\alpha-1)} di = (1-\xi_p)(1-n_{t-1}) Aux_{oldtech,t-1} . \quad (66)$$

Finally, the firms covered by the third integral have innovated and pushed the frontier, so that

$$\int_{1-n_{t-1}}^1 A_t(i)^{(1-\epsilon)(\alpha-1)} di = A_t^{max(1-\epsilon)(\alpha-1)} . \quad (67)$$

Referring to equations (66), (66), and (67), it follows that aggregate output must satisfy

$$P_t^\epsilon Y_t = \mu_{Z,t} \frac{K_t^\alpha L_t^{1-\alpha}}{Aux_{output,t}} , \quad (68)$$

where

$$\begin{aligned} Aux_{output,t} = & \xi_p(1-n_{t-1})(P_{t-1})^{-\epsilon} Aux_{oldtechnonreset,t-1} \\ & + (1-\xi_p)(1-n_{t-1}) F_t^{-\epsilon} Aux_{oldtech,t-1} \\ & + n_{t-1} F_t^{-\epsilon} (A_{t-1}^{max})^{(1-\epsilon)(\alpha-1)} . \end{aligned} \quad (69)$$

3.4 The aggregate resource constraint

Accounting for investment in $R\&D$, the aggregate resource constraint satisfies

$$C_t + I_t + a(u_t)\tilde{K}_t + X_t = Y_t, \quad (70)$$

since the sum of private consumption, investment, resources devoted to adjust the utilization rate of capital, and investment in $R\&D$ is bounded by the production of final goods.

3.5 General equilibrium and key Euler equations for the model to be solved

The general equilibrium of the model requires that supply and demand be equated for the final goods market, the intermediate goods market, the credit (bond) market, the labour market, the markets for physical capital, for investment in physical capital, as well as in $R\&D$. Appendix A collects all the relevant equations that need to be satisfied.

3.6 Detrending and model solution

In this model, output, consumption, physical capital, investments in physical capital and investments in research and development fluctuate around a balanced growth path because of technological growth. The existence of the balanced growth path is ensured by the use of labour augmenting technology.

The variables need to be detrended before simulating the model around the steady state. Detrending can be done either by dividing aggregate variables by the technological frontier or the average technology. Investments in $R\&D$ being a function of the technological frontier one could argue that detrending by the technological frontier is the correct way to do it. However, because aggregate output, investment and consumption are functions of the average prevailing technology level, we can also detrend by the average technology. In the context of an exogenous growth model, this question would be irrelevant since the frontier and the average technology are one and the same. Since we are interested in the implications of endogenous Schumpeterian growth for business cycles, we prefer to perform detrending with respect to the average technology level.

It can be shown that the average technology level \bar{A}_t is given by

$$\begin{aligned} \bar{A}_t &\equiv \int_0^1 A_t(i) di \\ &= n_{t-1}A_{t-1}^{max} + (1 - n_{t-1})n_{t-2}A_{t-2}^{max} + (1 - n_{t-1})(1 - n_{t-2})n_{t-3}A_{t-3}^{max} + \dots \\ &= n_{t-1}A_{t-1}^{max} + (1 - n_{t-1})\bar{A}_{t-1}. \end{aligned} \quad (71)$$

All variables with a trend, including the auxiliary variables, are made stationary, which generally requires the nominal variables to be divided by the product of P_t and some appropriate power of \bar{A}_t . Consequently, the detrending of many relevant variables involves the distance of a firm i 's technology level relative to the average technology level prevailing in the economy, i.e. $d_t(i) \equiv A_t(i)/\bar{A}_t$.

In particular, we can show that the detrended real marginal cost for firm i is given by

$$mc_t(i) = d_t(i)^{(\alpha-1)} \omega_t , \quad (72)$$

where $mc_t(i) \equiv MC_t(i)/P_t$, and $\omega_t \equiv \Omega/P_t \bar{A}_t^{(1-\alpha)}$, while its optimal relative reset price $\phi_t^*(i) \equiv P_t^*(i)/P_t$ is

$$\phi_t^*(i) = d_t(i)^{(\alpha-1)} f_t , \quad (73)$$

where $f_t \equiv F_t/\bar{A}_t^{(1-\alpha)}$.

Moreover, detrended real aggregate output amounts to

$$y_t = \frac{k_t^\alpha L_t^{(1-\alpha)}}{\int_0^1 d_t(i)^{(\alpha-1)} di} , \quad (74)$$

while detrended real investment in $R\&D$, $x_t \equiv X_t/\bar{A}_t$ is given by

$$x_t = \beta \frac{n_t}{1+\eta} \frac{\lambda_{t+1}}{\lambda_t} E_t v_{t+1}(A_t^{max}) , \quad (75)$$

with $\lambda_t \equiv \Lambda_t/(P_t \bar{A}_t)$, $E_t v_{t+1} \equiv E_t V_{t+1}(A_t^{max})/(P_{t+1} \bar{A}_{t+1})$.

Accordingly, the probability of innovating can be also written as

$$n_t = \left(\frac{x_t}{\zeta (\bar{A}_t/A_t^{max})^{-1}} \right)^{1/(1+\eta)} . \quad (76)$$

Once, the steady state of the detrended model is computed , the model is loglinearly-approximated around its steady state.

3.7 The New Keynesian Phillips curve

We now turn to the inflation dynamics in this economy with endogenous growth.¹⁴ Given the aggregate price index derived in equation (59), we use the properly detrended versions of the relevant variables to find an implicit dynamic equations for the inflation rate:

¹⁴Appendix B provides the definitions of the detrended variables and more details underlying the derivation of the New Keynesian Phillips curve.

$$\xi_p (1 - n_{t-1}) \pi_{t-1}^{\epsilon-1} = 1 - f_t^{1-\epsilon} \left((1 - \xi_p)(1 - n_{t-1}) a u x_{oldtech,t-1} + n_{t-1} d_t^{(\alpha-1)(\epsilon-1)} \right). \quad (77)$$

Then, referring to equation (33), the relevant factor in the optimal reset price is substituted into equation (77). Hence, the resulting equation can be rewritten as a first-order linear approximation in log-deviations from steady state, that yields the following New Keynesian Phillips curve for our model.

The New-Keynesian Phillips curve is a staple of New-Keynesian DSGE models, that relates inflation with the output gap (or real marginal cost gap) and expected future inflation. In our model, the introduction of endogenous growth further complicates this relationship and shows the existence of a link between inflation and technology. Indeed, the current rate of inflation is a function of the optimal reset price (through \hat{f}_t), the old technology still used in production ($a \hat{u} x_{oldtech,t-1}$), the growth rate of the frontier (\hat{g}_t) and the distance between the average technology and the frontier (\hat{d}_t).¹⁵

$$\hat{\pi}_t = \Gamma_1 \hat{f}_t + \Gamma_2 a \hat{u} x_{oldtech,t-1} + \Gamma_3 \hat{g}_t + \Gamma_4 \hat{d}_t, \quad (78)$$

These three additional variables also play an explicit role in a model with Schumpeterian innovation. First, as usual, a rise in the optimal reset price exerts a positive effect on inflation, with $\Gamma_1 \geq 0$. Second, the auxiliary variable reflecting the contribution from price resetting by some of the unsupplanted firms operating with prevailing older technology exerts also a positive effect on the inflation rate, since $\Gamma_2 \geq 0$. Third, growth in the technological frontier brings downward pressure on real marginal costs, that translates *ceteris paribus* in lower inflation, with $\Gamma_3 \leq 0$. Finally, $\Gamma_4 \leq 0$ can be intuitively understood from innovation pushing up the technological frontier, that hence increases the distance between A^{max} and the average technology level of firms operating in the economy, \bar{A}_t . This also reduces inflationary pressures.

Hence, in comparison with the standard New Keynesian DGSE model with exogenous output growth and no trend inflation, the price dynamics in our model involves an extended-like New Keynesian Phillips curve.

¹⁵ As defined in Appendix B, $d_t \equiv A_t^{max} / \bar{A}_t$.

4 Parameter Calibration and Characteristics of the Shocks

4.1 Taking the model to the data

Typically, a calibration exercise consists in restricting the values of the model parameters to target effectively a specified set of stylized facts or moments. Ensuring that the simulated data from the model are directly comparable with the empirical data is a crucial but often, rightly overlooked, step of the process, with not much consequences in an exogenous growth set-up. With Schumpeterian endogenous growth, this is not innocuous as it may well lead to a wrongful comparison.

Traditionally, simulated data around the model steady state are compared with the detrended empirical data. Such an oversight would be benign in the case of an exogenous growth model as growth is deterministic, with no built-in cyclical component. However, with endogenous growth, the growth rate of the economy is affected by cyclical components at medium frequencies. Therefore, a first step that is required is to rebuild the trending simulated data series by adding back the trend, namely

$$\ln(Y_t^{trending\ simulated}) = \ln(Y_t^{cyclical\ simulated}) + \ln(A_{t-1}) \quad (79)$$

By constructing a new set of trending simulated variables, we ensure comparability between model and empirical data. An HP filter is applied to both sets of data before the moments and comovements are generated.

While some parameters values were set on the basis of the usual values generally found in the literature, the other parameters in the calibration were based on the US data available for the 1960Q1 to 2018Q2 sample. We use [Fernald \(2017\)](#)'s data series on utilization-adjusted total factor productivity (TFP) to build a cumulative TFP series compounded at quarterly rates. Civilian non-institutional population is obtained from the U.S. Bureau of Labour and Statistics to compute the *per capita* variables. The Implicit Price Deflator is used as a proxy of the price level, and all macroeconomic aggregates originate from the U.S. Bureau of Economic Analysis. We use series on Real Gross Domestic Product, Research and Development, Real Gross Private Domestic Investment and Real Personal Consumption Expenditures.

4.2 Calibration associated with the features akin to that of a typical New Keynesian DSGE model

The calibration for most of the parameters pertaining to the New Keynesian aspects of the model is fairly standard. Table 1 presents the values used for calibration of key parameters of the model. The share of capital in the production function α , the discount rate β , the depreciation rate of physical capital δ as well as the monetary policy parameters are set to standard values in the literature. The steady-state gross trend inflation π is set at 1 (i.e. the inflation rate is zero in the steady-state). We also assume full capacity utilization in steady-state, i.e. $u = 1$. Market power in labour supply and

in the provision of intermediate goods leads to, generally agreed upon, wage and price markups of around 20% which is the benchmark in [Christiano et al. \(2005\)](#). This corresponds to an elasticity of substitution of 6 between intermediate goods, as well as between labour types. The disutility of labour θ is set so that steady state labour is approximately 0.33 of the hours endowment per period.

Finally, price changes are semi-endogenous in our model as, at any given period, two types of firms are allowed to reset prices, namely the innovative firms that implement a new product and the incumbent ones in operations that have been selected to do so.

4.3 Calibration associated with the Schumpeterian features of the model

Calibrating Schumpeterian models is a relatively new endeavour in economic research. We will base our calibration on the statistical moments of the variables related to research and development and technological advancement.

As shown in Figure 3, from 1960Q1 and 2018Q2, the share of GDP dedicated to *R&D* investment has varied between 2.22% and 2.96%, averaging a 2.68%-share of GDP over the period. We use this sample average as the steady state target for investment in *R&D* by calibrating the production function parameters at $\zeta = 10^8$ and $\eta = 11$.

Given the relationship between the frontier growth rate, the spillover and the innovation probability, there are additional degrees of freedom left as the variation along one dimension can be compensated by a change in another. This additional degree of freedom will prove particularly interesting when studying the dynamics of the model. For instance, different restrictions will yield significantly different impulse response functions.

4.4 Persistence and variance of the shocks

Investment and monetary policy shocks parameters, shown in Table 2, are derived from New Keynesian literature and find their sources in [Justiniano et al. \(2010\)](#). The spillover and transitory technology shocks are two components of TFP. The transitory technology shock can be seen as the cyclical component of TFP. We, therefore, calibrate both persistence and volatility to match the cyclical component of TFP. We, then, perform a grid search to minimize the Euclidian distance between the volatilities of observed and simulated TFP. The results from this calibration are reported in Table 3.

In the next section, we show that our model exhibits relative volatilities, correlations and autocorrelations consistent with the observed data.

5 Consistency of the Theoretical Model With the Data

Although the calibration we have adopted was not aiming at replicating with precision the sample statistical moments observed in the data, comparing some key moments of the HP cyclical components of simulated and empirical data allows to check the consistency of the mechanisms built in the model. Tables 4, 5 and 6 show relative volatilities, contemporaneous correlations and autocorrelations for various macroeconomic variables.¹⁶

As shown in Table 4, the simulated relative volatilities to that of output are fairly consistent with their sample counterparts. In particular, the model quite closely matches the volatility of $R\&D$. As expected, both investment in physical capital and investment in $R\&D$ are more volatile than output respectively with relative volatilities given by 2.17 and 0.96. Cyclical consumption is somewhat more volatile in the model than in the data, and investment in physical capital is somewhat too volatile in comparison with the data.¹⁷ Moreover, the price level and the inflation rate in the model exhibit respectively a little less and a little more volatility than in the observed data.

The signs and the sizes of various contemporaneous correlations between the HP cyclical components of the macroeconomic variables presented in Table 5 are fairly similar in both empirical and simulated data, albeit they often appear to be a bit greater for the simulated series. For instance, simulated correlations between $R\&D$ investment and output, and $R\&D$ and consumption are 0.68 and 0.58 compared with 0.40 and 0.41 in the data. It is particularly worth pointing out that the values of contemporaneous correlation between the price level and the various macroeconomic variables are negative and closely their empirical counterparts. At the same time, the values of the correlation between the inflation rate and the other variables are relatively weak between -0.18 and 0.23, so that the observed discrepancy may not be that important.¹⁸

Finally, Table 6 presents the autocorrelation coefficients at order 1 to 4 for the cyclical components of the macroeconomic variables. The model tends to replicate reasonably well the empirical autocorrelations of the variable. This is especially so for the autocorrelation of consumption, while the model shows a little more persistence in output, investments in physical capital, and inflation. It shows a little less persistence in $R\&D$ investment and the price level.

With a reasonable calibration of the model, it is thus possible to get key moments and comovements for important macroeconomic variables that are consistent with their observed counterparts.

¹⁶Given the computing power at our disposal, and using a grid search approach, we made (at this time) a compromise between processing time and accuracy. This could subsequently be the object of further refinements.

¹⁷By resorting to a smaller increment in the grid-search procedure, and by adjusting the parameters for intensity parameter of habit persistence in consumption as well as the convex adjustment cost of investment in physical capital, it is likely that the moments for the simulated data get closer to the empirical moments (Though this is not our objective here).

¹⁸We intend to calculate the standard errors of these moments in our next revision.

6 The Business Cycle Implications of Varying the Steady-State Probabilities of Innovating

In our model, the balanced growth rates of the technological frontier and of the trend growth rate of real output are determined by the product of both the steady-state probability of innovating, n_{ss} , and the steady-state extent of technology spillover, σ_{ss} , as the latter induces a larger technological jump of the frontier. Hence,

$$g_{ss} = 1 + \sigma_{ss} n_{ss} . \quad (80)$$

Namely, it is therefore possible to consider different combinations of n_{ss} and σ_{ss} , that generate the same value of g_{ss} . However, existing evidence in the literature does not carry much information about how to calibrate σ_{ss} versus n_{ss} .¹⁹

Nonetheless, at this stage, it is instructive to consider how the impulse response functions of the macroeconomic variables to each shocks differ when comparing two economies. In the first one, we fix $n_{ss} = 0.05$ and $\sigma_{ss} = 0.097$, while in the second one, these are respectively set as $n_{ss} = 0.35$ and $\sigma_{ss} = 0.0139$. Hence, both economies are consistent with a steady-state quarterly gross growth rate given by $g_{ss} = 1.00485$ or approximately 2% *per annum*. The former economy is therefore associated with a lower a probability of innovating, typically linked with a “bigger” jump, while the latter is characterized by more frequent, yet smaller, discoveries that are more easily spread, so that they do not require as big a value for σ_{ss} .

Although we keep invariant the steady state real growth rate of output, a different steady-state probability of innovation has a specific impact on the dynamics of the economy, that was absent in the usual model with exogenous growth. Indeed, in our setup, a larger value of n_{ss} implies not only that a greater proportions of intermediate firms will be innovating in the steady state, but also that the extent of effective price flexibility is higher as the proportion of firms that proceed with a reoptimization of the intermediate good prices has risen. That is, since innovating firms are allowed to set the optimal mark-up pertaining to the innovating intermediate product.

We now discuss how the impulse response functions of the cyclical macroeconomic variables following different shocks are altered when considering a “low” steady-state probability of innovation, say 5%, *versus* an economy with a relatively “high” steady-state probability of innovation, say 35%.

¹⁹Moreover, in the real world, some variety across industries, as well as various era may imply that this decomposition may well differ across time. This would introduce another level of interesting complexity over a long span of data, that is beyond the scope of the current paper.

6.1 The impulse response functions following a transitory technology shock

As can be seen in Figures 4 and 5, when changing n_{ss} from 5% to 35%, a positive transitory technology shock does not lead to a very significantly different cyclical dynamics on output, consumption, investment in physical capital, hours worked, capacity utilization, physical capital stock and the optimal reset price. However, this does not mean that it is without consequences. Initially, a cyclical wealth effect dominates on hours worked, while it builds up on consumption. Then, the cyclical intratemporal and intertemporal substitution effects on hours worked takes the lead. Also, as expected the rise in the marginal product of physical capital first leads to a positive cyclical response of capacity utilization, while the increased incentive to invest in physical capital peaks up and start to rise its stock.

With $n_{ss} = 0.35$, there is a sharper immediate negative response of inflation and drop in nominal interest rates lasting a few quarters. Also, the induced rise in the marginal productivities of labour and capital translates into transitory positive cyclical impacts on the wage index, the optimal reset wage and the return on physical capital. Furthermore, this positive transitory positive technology shock has a transitory, albeit persisting beyond 25 quarters on investments into the value of an intermediate firm, $R\&D$ investments, the innovation probability, and finally average real growth.

6.2 The impulse response functions following an efficiency of investment shock

After a temporary positive improvement on the efficiency of investment in physical capital, a quick temporary rise in the return on physical capital follows, that quickly brings up temporarily cyclical capacity utilization and private investment. The increase in optimal reset wage and return on capital both push the marginal cost up through the dynamic complementarity of inputs.

The cyclical impulse response functions in Figures 6 are not much different whether $n_{ss} = 0.05$ or $n_{ss} = 0.35$.

As shown in the lower panel of Figure 7, when $n_{ss} = 0.35$, a positive shock on the efficiency of investment leads to a persistent cyclical increase in the probability of innovating, in the discounted expected value of the intermediate firms, and in $R\&D$ investments. Here too, the average growth rate of real output also exhibits a persistent cyclical increase.

6.3 The impulse response functions following a monetary policy shock

We now turn to the cyclical impact of a restrictive monetary policy, brought about by a “discretionary” rise in the nominal interest above the Taylor-type reaction function. The net effect on the nominal interest rate therefore is the combination of the monetary shock and the immediate reaction to inflation- and output-growth gaps. As illustrated in Figure 8, the nominal interest rate initially goes up, while the inflation rate goes down. This is accompanied by a quick cyclical downturn in real output, in consumption, in hours worked, in capacity utilization and in investment in

physical capital, along with a cyclical decrease in the real return on capital. A higher steady-state innovation-probability value of $n_{ss} = 0.35$, compared with $n_{ss} = 0.05$, generally leads to somewhat weaker cyclical fluctuations in the above variables, except for inflation that is brought down more quickly.

At the same time, there is a smaller negative cyclical impact on marginal cost, while the wage index temporarily goes up, even though the optimal reset wage is cyclically lower.

Meanwhile, this restrictive policy shock causes a fairly more important cyclical downturn in the probability of innovating that lowers a little more the value of intermediate firms and investments in *R&D*. However, despite these consequences, the cyclical impact of average real growth rate does not differ as much with either $n_{ss} = 0.35$ or $n_{ss} = 0.05$. The cumulative impact of lower compounded growth is not necessary negligible however. This still needs to be assessed.

6.4 The impulse response functions following a knowledge-spillover shock

The last shock to be considered is specific to a model with endogenous growth and has no analogue in exogenous growth business cycle models.

As it is apparent in Figures 10 and 11, the cyclical dynamic responses to a transitory positive knowledge-spillover shock is significantly sensitive to the steady-state probability of innovation. Focussing first our attention to Figure 11, an increased extent of knowledge-spillover cyclically lowers for some quarters both the value of intermediate firms' discounted profits and investments in *R&D*, while cyclically lowering the probability of innovation. However, the cyclical impacts on the innovation probability and the average real output growth rate are fairly subdued when $n_{ss} = 0.05$. This is not so for $n_{ss} = 0.35$. Instead, the positive cyclical response of the average growth rate is much higher and more persistent. Moreover, in this case, for about 5 quarters, there initially is a bigger decrease in each of the investment in *R&D*, the value of the discounted firm and the probability of innovation, then followed by a positive 4- to 5-quarter rise in these variables, prior to a sustained but slight negative impact.

Now considering the cyclical impulse responses of the other macroeconomics variables, an appreciably higher value of n_{ss} , such as 35%, leads to significantly more volatile cyclical effects of a given positive knowledge-spillover shock, as there are, in part, stronger intertemporal substitution effects that are engineered by this shock. To some extent, as seen in Figure 10, it is as if the cyclical impulse response functions are somewhat squeezed for many graphics for a higher value of n_{ss} .

There are two main conclusions we can draw from the impulse response function to the spillover shock. The spillover shock could be the main source of cyclical fluctuation of the growth rate of the economy. An estimated model would allow to compute the variance decomposition and confirm the intuition gathered from the impulse response functions. A larger innovation probability at the steady state quickens the model's reaction to a spillover shock. Most variables such as the nominal

interest rate and the optimal reset price return to their steady state much quicker when $n_{ss} = 35\%$. We will now turn to an assessment of the welfare implications of various (σ_{ss}, n_{ss}) pairs. It can be expected that two effects will be in play. On one hand, if a higher value of n_{ss} brings about more volatility of cyclical consumption, this will lower welfare. On the other hand, if it raises trended permanent income, and therefore trend consumption, it will be welfare-raising.

7 The Welfare Implications of Different Steady-State Probability of Innovation

In our model, the innovation probability is the odds that, for a given amount of investments in $R\&D$, the process is successful in introducing a new technology. For the firm in monopolistic position in its sector, it also corresponds to the probability of being supplanted by an innovator. As such, this can be seen as the proportion of firms that enters or exits the unit mass intermediate sector.

Having looked at the impulse response functions of a New Keynesian model with endogenous growth, we now turn to the welfare implications of the interaction between business cycles and endogenous growth. Our aim is to assess the welfare cost of different calibrations of the Schumpeterian growth mechanisms, while keeping constant the steady-state growth rate of the technological frontier. Since $g_{ss} = 1 + \sigma_{ss}n_{ss}$, both n_{ss} and σ_{ss} can be varied while keeping g_{ss} invariant, in order to study the welfare implications of different combinations of steady-state probability of innovation and spillover. For instance, a high degree of knowledge-spillover can compensate for a lower innovation probability.

The infinite-horizon sum of the present discounted value of flow utilities across households define their welfare, which can be recursively expressed as follows:

$$\mathcal{W}_t = U(C_t, L_t) + \beta \mathcal{W}_{t-1}. \quad (81)$$

Accordingly, applying the methodology developed by [Schmitt-Grohé and Uribe \(2004\)](#), it is possible to make welfare comparisons between a benchmark scenario for the (n_{ss}, σ_{ss}) -pair, indexed by subscript B , and alternative pairs, generically indexed by subscript A . We choose to contrast various scenarios relative to a benchmark using consumption-equivalent differences as a more tangible measure of welfare. Namely, it is thus expressed as a percentage of steady state consumption that would make a household indifferent between two scenarios.

A first measure, evaluated at the non-stochastic steady states, reckons the fraction of consumption that would have to be given up each period in the alternative scenario to reach the same welfare level as in the benchmark scenario. It is defined as:

$$\mathcal{C}_{ss} = 1 - \exp\left((1 - \beta) \cdot [\mathcal{W}_{B,ss} - \mathcal{W}_{A,ss}]\right) \quad (82)$$

where $\mathcal{W}_{B,ss}$ is the benchmark and $\mathcal{W}_{A,ss}$ is the alternative. Accordingly, when $\mathcal{W}_{B,ss} < \mathcal{W}_{A,ss}$, then $\mathcal{C}_{ss} > 0$.

A second measure can also be evaluated at stochastic means of the value functions obtained from the model simulations. It hence takes into account the interaction between the alternative (n_{ss}, σ_{ss}) -pair interacts with the various random shocks built-in the model. In this case, the corresponding consumption-equivalent welfare loss is given by:

$$\mathcal{C}_m = 1 - \exp\left((1 - \beta) \cdot [E(\mathcal{W}_{B,t}) - E(\mathcal{W}_{A,t})]\right) \quad (83)$$

with $\mathcal{C}_m > 0$ when $E(\mathcal{W}_{B,t}) < E(\mathcal{W}_{A,t})$.

As previously mentioned, different combinations of (n, σ) , that yield a yearly steady-state gross growth rate of $g_{ss} = 1.01954$ *per annum*, are used to compute and to compare the non-stochastic steady-state and stochastic-means consumption-equivalent welfare measures. While the former (\mathcal{C}_{ss}) is obtained directly, the latter first requires to compute the stochastic means of the variables of interest prior to calculating \mathcal{C}_m .

Since $\sigma_{ss} = \frac{g_{ss}-1}{n_{ss}}$, for the calibrated value of $g_{ss} = 1.00485$ per quarter, we set the benchmark calibration at a quarterly steady-state innovation probability of $n_{ss} = 0.15$, along with $\sigma_{ss} = 0.3233$. For the alternative scenarios, the innovation probability n are varied from 0.16 to 0.54. The corresponding spillover parameter σ_{ss} is changed accordingly from 8.9815×10^{-3} to 3.0313×10^{-2} . Figure 12 shows the results from these simulations.

There are two main conclusions. First, the welfare impact of varying the steady-state innovation probability, even for a constant value of g_{ss} is non negligible. Indeed, to be indifferent between an innovation probability given by $n_{ss} = 0.15$ instead of $n_{ss} = 0.23$, a household would have to be compensated with a higher steady state consumption of 2.0% according to the non-stochastic the steady-state measure, and 4.7% according to the stochastic-means measure. Second, there is significant non linearity when comparing the welfare impact of different (n_{ss}, σ_{ss}) environments. Indeed, the consumption-equivalent welfare-comparison curve is positively sloped and steeper between $n_{ss} = 0.16$ and $n_{ss} = 0.2$. It reaches a maximum at $n_{ss} = 0.23$, before slowly decreasing.

Two opposing forces are simultaneously at work in determining welfare. On the one hand, an increase in the steady-state innovation probability leads to a greater turnover in firms who set prices more often. As it is even more strongly revealed by the \mathcal{C}_m measure, a higher value for n_{ss} allows the model economy to be closer to an economy without any price rigidities. Indeed, the reduction in the price wedge is welfare improving. On the other hand, when the innovator decides how much to invest in R&D, only private benefits are taken into account. Since an increase in the innovation probability amounts also to a lower probability for an incumbent to remain in operation, this reduces the discounted value of the innovation, with its consequential reduction in welfare.

Hence, there is also a positive externality from innovating that is not considered by the private innovator, while the society benefits from additional permanent push of the technological frontier. From a normative angle, The larger the gap between the private and social values of innovating, the more investment in R&D is socially suboptimal. This suggests some issues worth considering in future research on the appropriate length of intellectual property right policy.

8 Conclusion

Despite the development of modern endogenous growth models, commonly used DSGE business cycle models are based on an exogenous neoclassical long-term growth and focus only on the fluctuations around that trend growth. By embedding Schumpeterian innovation into the intermediate production sector within a New Keynesian model with nominal wage and price stickiness, we show that endogenous decisions to invest in *R&D* have implications that impact the likelihood of innovating and pushing the technological frontier, while adding a relevant transmission channel for common shocks (such as aggregate technological, investment efficiency and monetary shocks), as well as for a spillover shock, that was absent in models with exogenous growth. In fact, the interplay of innovation with optimal price-setting in the intermediate sector both spells out how the technological frontier advances, but also implies that more innovation leads to more price flexibility in a world with nominal rigidities.

From a theoretical stance, we show that our hybrid model highlights and addresses new challenges at the modelling and simulation stages. First, the investment decisions in *R&D* need to account for the interactions between both the endogenous growth features and the New Keynesian characteristics of the model. Indeed, the expected discounted profits arising from an innovation is affected both by the probability of being supplanted by a new innovator and, if, not supplanted, the probability that the price can be optimally reset in periods subsequent to an innovation. This has implications for the aggregation of the intermediate production sector. Second, the introduction of Schumpeterian innovation, that determines the expected growth rate of the economy, makes it conceivable to consider the implications of knowledge spillover shocks, as an additional dimension not found in the usual business cycle models. This new shock is interpreted as the unpredictable variations and other heterogeneities in the transmission of knowledge and/or abilities to capitalize on new innovations to push the technological frontier further.

From a methodological point of view, it is shown that the computation, presentation and interpretation of the impulse response functions need to be seen differently, when accounting jointly for endogenous growth and business cycles. Namely, the cyclical IRFs of endogenous and exogenous growth models are not directly comparable. The nature of exogenous growth makes it entirely acyclical while endogenous growth rates vary cyclically around a steady state.

Regarding the ability of the model to replicate key stylized business cycle characteristics, adopting a reasonable calibration in line with usual practices, given the arbitrage currently made between accuracy and processing times, we find that the model can produce moments and comovements relating to output, consumption, investment in physical capital and investment in $R\&D$ that are consistent with their empirical counterparts.

Relative to their respective relevant trend, the aggregate business cycles responses to the common shocks defined as disturbances on aggregate productivity, investment efficiency or monetary policy remain quite quantitatively similar in both models with endogenous and exogenous growth, in case where the steady-state probability of innovating in a quarter is fairly small (e.g. 5%). With endogenous Schumpeterian growth, however, a new knowledge-spillover shock, while sensitive to calibration, allows additional insight into the average growth rate of the economy at different frequencies, even beyond those typically considered in the literature. This suggests other dimensions worth pursuing in future research.

Moreover, we have shown that the dynamic responses of macroeconomic variables may differ significantly in amplitude and shape-wise if we vary the steady-state probability of innovating, yet keeping constant the steady-state or trend growth rate of real output. This arises because a higher steady-state probability of innovating, typically linked with a “smaller” jump of the technological frontier, is associated with a smaller steady-state extent of technology spillover, i.e. smaller discoveries are more easily spread. However, a new key mechanism is revealed as a higher probability of innovating also diminishes the extent of nominal price rigidities, since incoming innovating firms are allowed to set an optimal price.

Thus, there are important welfare implications of different combinations of steady-state innovation probability and extent of knowledge-spillover, even for the same 1.95% *per annum* value for steady-state growth of the technological frontier. In particular, an economy with a 23% steady-state quarterly probability of innovating rather than 15%, accounting for dynamic interactions, has a consumption-equivalent impact on welfare of a 4.7% higher level.

This arises as innovation and the degree of price flexibility are tied, and we show that this may not be innocuous for both efficiency and welfare. It is likely that the measured welfare impact in our model is an upper bound. For instance, instead of having a new innovative intermediate firm i kicking out and replacing a now obsolete i^{th} -intermediate good producer, some lagging and advanced firms might coexist for a while.²⁰ This might then reduce the enhanced price flexibility. Furthermore, to the extent that the steady-state growth rate of the technological frontier would have diminished along with a lower steady-state probability of innovation, it would be interesting

²⁰Since we have focused on vertical innovations, this might be more so with horizontal innovations.

to assess the impact of the accompanying reduced price flexibility both at a new steady state and in the transition from the older to the newer steady state. Still, we show that the interplay between innovation and price setting deserves further attention, notably in the context of new technologies that will alter the economic landscape.²¹

Finally, many new questions, that could not be raised in standard DSGE New Keynesian models, will deserve future work and are brought to the fore by possible extensions to our model. The following list include some of them. How important are the mismeasurements of inflation and of effective real growth due to the growth and business cycle implications of innovation? How should optimal monetary policy be modelled in an environment accounting for innovation? Should the monetary authority's reaction respond differently according to the source of the output and the inflation fluctuations? What are the business cycle and growth implications of fiscal policy in this context, including how should we assess different government policies intended to encourage innovation? What would be the business cycle, growth and welfare implications of transiting from a higher to a lower steady-state growth rate of the technological frontier?

²¹As an example, the president of GM recently argued about the impact of an increased adoption of electric and self-driving vehicles with a lower cost of operation as their purchase prices will drop as “each generation of battery technology [ans vehicles] improves efficiency and reduces cost.” See [Reuss \(2019\)](#).

Parameter	Value	Description
α	1/3	Share of capital in intermediate-good production
β	.99	Discount rate
δ	.025	Depreciation rate of physical capital
π	1	Steady-state gross inflation rate
u	1	Steady-state capacity utilization rate
ϵ	6	Elasticity of substitution of intermediate-good demand
γ	6	Elasticity of substitution of labour demand
ξ_p	$1 - \frac{(1-.66)}{(1-n_{ss})}$	Calvo parameter for prices
ξ_w	.66	Calvo parameter for wages
θ	5	Weight on the disutility of labour
ν	1	Utility parameter that determines the Frisch elasticity of labour supply, $(\frac{1}{\nu})$
h	.5	Consumption habit formation
κ	1	Investment adjustment-cost parameter
σ_{ss}	$\frac{(g_{ss}-1)}{n_{ss}}$	Steady-state value for the extent of knowledge-spillover
ζ	10^8	Scaling parameter in the innovation production function
η	11	Diminishing-return parameter in the innovation production function

Note: As explained further below, the joint determination of n_{ss} and σ_{ss} is made to replicate the long-run value of the growth rate of the technological frontier g_{ss} , that is set at the historical average of real GDP *per capita* from 1960Q1 to 2018Q2.

TABLE 1: Calibration of key parameters

A – The Set of Equilibrium and Optimality Equations

In the equations below, Λ_t and Φ_t are the Lagrange multipliers associated respectively with the household's budget constraint equation (14), and the investment equation (15) at date t .

$$\frac{1}{C_t - hC_{t-1}} - \Lambda_t P_t - \beta \frac{h}{C_{t+1} - hC_t} = 0 \quad (\text{A1})$$

$$-\frac{\Lambda_t}{1 + r_t} + \beta \Lambda_{t+1} = 0 \quad (\text{A2})$$

$$q_t - P_t a'(u_t) = 0 \quad (\text{A3})$$

$$-\Lambda_t P_t + \Phi_t \mu_t \left[\frac{I_t}{I_{t-1}} S' \left(\frac{I_t}{I_{t-1}} \right) + 1 - S \left(\frac{I_t}{I_{t-1}} \right) \right] + \beta \Phi_{t+1} \mu_{t+1} \frac{I_{t+1}^2}{I_t^2} S' \left(\frac{I_{t+1}}{I_t} \right) \quad (\text{A4})$$

$$-\Phi_t + \beta \Lambda_{t+1} (q_{t+1} u_{t+1} - P_{t+1} a(u_{t+1})) + \beta \Phi_{t+1} (1 - \delta) = 0 \quad (\text{A5})$$

$$K_t = u_t \tilde{K}_t . \quad (\text{A6})$$

$$W_t^*(j)^{-\gamma\nu-1} = \frac{\gamma-1}{\theta\gamma} \frac{Aux_{bc,t}}{Aux_{dis,t}} \quad (\text{A7})$$

$$\frac{K_t}{L_t} = \frac{\alpha}{1-\alpha} \frac{W_t}{q_t} \quad (\text{A8})$$

$$F_t = \frac{\epsilon}{\epsilon-1} \frac{Aux_{cost,t}}{Aux_{rev,t}} \quad (\text{A9})$$

$$n_t = \left(\frac{X_t}{\zeta A_t^{max}} \right)^{1/(1+\eta)} \quad (\text{A10})$$

$$A_t^{max} = g_t^{max} \cdot A_{t-1}^{max} \quad (\text{A11})$$

$$g_t^{max} = 1 + \sigma_t n_{t-1} \quad (\text{A12})$$

$$X_t = \beta \frac{n_t}{1+\eta} \frac{\Lambda_{t+1}}{\Lambda_t} \frac{E_t V_{t+1} (A_t^{max})}{P_t} . \quad (\text{A13})$$

$$E_t V_{t+1} = A_t^{max(\alpha-1)(1-\epsilon)} \cdot (F_{t+1}^{1-\epsilon} Aux_{rev,t+1} - F_{t+1}^{-\epsilon} Aux_{cost,t+1} + Aux_{rem,t+2}) \quad (\text{A14})$$

$$P_t^{1-\epsilon} = \xi_p (1 - n_{t-1}) (P_{t-1})^{1-\epsilon} + (1 - \xi_p) (1 - n_{t-1}) F_t^{1-\epsilon} Aux_{oldtech,t-1} + n_{t-1} A_{t-1}^{max(\alpha-1)(\epsilon-1)} F_t^{1-\epsilon} \quad (\text{A15})$$

$$W_t^{1-\gamma} = \xi_w (W_{t-1})^{1-\gamma} + (1 - \xi_w) W_t^{*1-\gamma} \quad (\text{A16})$$

$$P_t^\epsilon Y_t = \mu_{z,t} \frac{K_t^\alpha L_t^{1-\alpha}}{Aux_{output,t}} \quad (\text{A17})$$

$$C_t + I_t + a(u_t) \tilde{K}_t + X_t = Y_t, \quad (\text{A18})$$

$$\frac{1+R_t}{1+R} = \left(\frac{1+R_{t-1}}{1+R} \right)^{\rho_R} \left[\left(\frac{\pi_t}{\pi} \right)^{\alpha_\pi} \left(\frac{Y_t}{Y_{t-1}} g^{-1} \right)^{\alpha_y} \right]^{1-\rho_R} \mu_{M,t} \quad (\text{A19})$$

Auxiliary variables:

$$Aux_{bc,t} = \Lambda_t W_t^\gamma L_t + \xi_p \beta Aux_{bc,t+1}, \quad (\text{A20})$$

$$Aux_{dis,t} = \Lambda_t W_t^{\gamma(1+\nu)} L_t^{1+\nu} + \xi_p \beta Aux_{dis,t+1}. \quad (\text{A21})$$

$$Aux_{rev,t} = P_t^\epsilon Y_t + \xi_p \beta \frac{\Lambda_{t+1}}{\Lambda_t} (1 - n_t) Aux_{rev,t+1}, \quad (\text{A22})$$

$$Aux_{cost,t} = \Omega_t P_t^\epsilon Y_t + \xi_p \beta \frac{\Lambda_{t+1}}{\Lambda_t} (1 - n_t) Aux_{cost,t+1}. \quad (\text{A23})$$

$$Aux_{rem,t+2} = (1 - \xi_p) \beta^2 \frac{\Lambda_{t+2}}{\Lambda_{t+1}} (F_{t+2}^{(1-\epsilon)} Aux_{rev,t+2} - F_{t+2}^{-\epsilon} Aux_{cost,t+2}) \quad (\text{A24})$$

$$Aux_{oldtech,t-1} = n_{t-2} A_{t-2}^{max(\alpha-1)(1-\epsilon)} + (1 - n_{t-2}) Aux_{oldtech,t-2} \quad (\text{A25})$$

$$\begin{aligned} Aux_{output,t} &= \xi_p (1 - n_{t-1}) (P_{t-1} \pi_{p,t-1,t})^{-\epsilon} Aux_{oldtechnonreset,t-1} \\ &\quad + (1 - \xi_p) (1 - n_{t-1}) F_t^{-\epsilon} Aux_{oldtechreset,t-1} \\ &\quad + n_{t-1} F_t^{-\epsilon} (A_{t-1}^{max})^{(1-\epsilon)(\alpha-1)} \end{aligned} \quad (\text{A26})$$

$$Aux_{oldtechnonreset,t} = n_{t-1} A_{t-1}^{max \alpha - 1} + (1 - n_{t-1}) Aux_{oldtechnonreset,t-1} \quad (\text{A27})$$

Laws of motions for the various stochastic shocks:

$$\ln \mu_{I,t+1} = \rho_I \ln \mu_{I,t} + \epsilon_{I,t} \quad (\text{A28})$$

$$\ln \mu_{Z,t} = \rho_Z \ln \mu_{Z,t-1} + \epsilon_{Z,t} \quad (\text{A29})$$

$$\ln \sigma_t = \ln \sigma + \rho_\sigma \ln \sigma_{t-1} + \epsilon_{\sigma,t} \quad (\text{A30})$$

$$\ln \mu_{M,t} = \rho_M \ln \mu_{M,t-1} + \epsilon_{M,t} \quad (\text{A31})$$

B – The New Keynesian Phillips Curve

B.1 Detrended variables

The first step to derive the Phillips curve is to detrend the relevant variables of the model:

$$y_t \equiv \frac{Y_t}{A_t^{1-\alpha}} \quad (\text{B1})$$

$$f_t \equiv \frac{F_t}{A_t^{1-\alpha} P_t} \quad (\text{B2})$$

$$aux_{cost,t} \equiv \frac{Aux_{cost,t}}{A_t^{2-\alpha} P_t^{1+\epsilon}} \quad (\text{B3})$$

$$aux_{rev,t} \equiv \frac{Aux_{rev,t}}{A_t P_t^\epsilon} \quad (\text{B4})$$

$$\omega_t \equiv \frac{\Omega_t}{A_t^{1-\alpha}} \quad (\text{B5})$$

$$aux_{oldtech,t} \equiv \frac{Aux_{oldtech,t}}{A_t^{(\alpha-1)(1-\epsilon)}} \quad (\text{B6})$$

$$\lambda_t \equiv \Lambda_t A_t^{max} P_t \quad (\text{B7})$$

B.2 Detrended optimal reset price and marginal cost

Then, detrending the optimal reset price and approximating it around the steady state implies:

$$f_t = \frac{\epsilon}{\epsilon - 1} \frac{aux_{cost,t}}{aux_{rev,t}} \quad (\text{B8})$$

$$aux_{cost,t} = \omega_t y_t + \frac{\xi_p \beta \lambda_{t+1}}{\lambda_t} g_t^{1-\alpha} \pi_{t+1}^\epsilon (1 - n_t) aux_{cost,t+1} \quad (\text{B9})$$

$$aux_{revt} = y_t + (1 - n_t) \frac{\xi_p \beta \lambda_{t+1}}{\lambda_t} \pi_{t+1}^{\epsilon-1} aux_{revt+1} \quad (B10)$$

B.2.1 Auxiliary variable for cost

Using the following steady state values

$$aux_{cost} = \omega y + \xi_p \beta g^{1-\alpha} \pi^\epsilon (1 - n) aux_{cost} , \quad (B11)$$

$$(1 - \xi_p \beta g^{1-\alpha} \pi^\epsilon (1 - n)) aux_{cost} = \omega y , \quad (B12)$$

$$aux_{cost} = \frac{\omega y}{1 - \xi_p \beta g^{1-\alpha} \pi^\epsilon (1 - n)} , \quad (B13)$$

we find:

$$\begin{aligned} \widehat{aux}_{cost,t} &= \frac{\omega y}{aux_{cost}} (\widehat{\omega}_t + \widehat{y}_t) \\ &\quad - \frac{aux_{cost} - \omega y}{aux_{cost}} \left[\frac{n}{1 - n} \widehat{n}_t + \widehat{aux}_{cost,t+1} - \widehat{\lambda}_t + \widehat{\lambda}_{t+1} + \epsilon \widehat{\pi}_{t+1} + (1 - \alpha) \widehat{g}_{t+1} \right] \end{aligned} \quad (B14)$$

B.2.2 Auxiliary variable for revenue

Using the following steady state values

$$aux_{rev} = y + (1 - n) \xi_p \beta \pi^{\epsilon-1} aux_{rev} , \quad (B15)$$

$$(1 - (1 - n) \xi_p \beta \pi^{\epsilon-1}) aux_{rev} = y , \quad (B16)$$

$$aux_{rev} = \frac{y}{1 - (1 - n) \xi_p \beta \pi^{\epsilon-1}} , \quad (B17)$$

we find:

$$\widehat{aux}_{rev,t} = \frac{y}{aux_{rev}} \widehat{y}_t - \frac{aux_{rev} - y}{aux_{rev}} \left[\frac{n}{1 - n} \widehat{n}_t + \widehat{aux}_{cost,t+1} - \widehat{\lambda}_t + \widehat{\lambda}_{t+1} + (\epsilon - 1) \widehat{\pi}_{t+1} \right] \quad (B18)$$

B.3 From the price index to the inflation rate equation

Using the price index, we derive a log-linearized approximation of inflation around the steady state.

The price index equation:

$$P_t^{1-\epsilon} = \xi_p(1 - n_{t-1})P_{t-1}^{1-\epsilon} + (1 - \xi_p) \int_{n_{t-1}}^1 P_t^{*1-\epsilon}(i)di + \int_0^{n_{t-1}} P_t^{*}(i)^{1-\epsilon} \quad (\text{B19})$$

$$P_t^{1-\epsilon} = \xi_p(1 - n_{t-1})P_{t-1}^{1-\epsilon} + (1 - \xi_p)(1 - n_{t-1})F_t^{1-\epsilon}Aux_{oldtech,t-1} + n_{t-1}F_t^{1-\epsilon}A_{t-1}^{max(\alpha-1)(\epsilon-1)} . \quad (\text{B20})$$

Corresponding inflation equation (after detrending):

$$\xi_p(1 - n_{t-1})\pi_{t-1}^{\epsilon-1} = 1 - f_t^{1-\epsilon} \left((1 - \xi_p)(1 - n_{t-1})aux_{oldtech,t-1} + n_{t-1}d_t^{(\alpha-1)(\epsilon-1)} \right) \quad (\text{B21})$$

or, alternatively,

$$\xi_p\pi_{t-1}^{\epsilon-1} = (1 - n_{t-1})^{-1} - f_t^{1-\epsilon} \left((1 - \xi_p)aux_{oldtech,t-1} + \frac{n_{t-1}}{1 - n_{t-1}}d_t^{(\alpha-1)(\epsilon-1)} \right) . \quad (\text{B22})$$

The distance between the average technology and the frontier:

$$\bar{A}_t = n_{t-1}A_t^{max} + (1 - n_{t-1})\bar{A}_{t-1} \quad (\text{B23})$$

$$\frac{\bar{A}_t}{A_t^{max}} = n_{t-1} + (1 - n_{t-1})\frac{\bar{A}_{t-1}}{A_t^{max}} \quad (\text{B24})$$

$$d_t \equiv \frac{A_t^{max}}{\bar{A}_t} \quad (\text{B25})$$

$$d_t^{-1} = n_{t-1} + (1 - n_{t-1})d_{t-1}^{-1}g_t^{-1} . \quad (\text{B26})$$

The gross growth rate of the technological frontier:

$$g_t = 1 + \sigma_t n_{t-1} \quad (\text{B27})$$

$$n_{t-1} = \frac{g_t - 1}{\sigma_t} . \quad (\text{B28})$$

The inflation rate equation can be rewritten as a follows:

$$\xi_p \left(1 - \frac{g_t - 1}{\sigma_t} \right) \pi_{t-1}^{\epsilon-1} \quad (\text{B29})$$

$$= 1 - f_t^{1-\epsilon} \left((1 - \xi_p) \left(1 - \frac{g_t - 1}{\sigma_t} \right) aux_{oldtech,t-1} + \frac{g_t - 1}{\sigma_t} \left(\frac{g_t - 1}{\sigma_t} + \left(1 - \frac{g_t - 1}{\sigma_t} \right) d_{t-1}^{-1} g_t^{-1} \right)^{(1-\alpha)(\epsilon-1)} \right) .$$

Finally, the linear approximation around the steady state brings leads to the following version of the New Keynesian Phillips curve:

$$\begin{aligned}
\hat{\pi}_t = & - \frac{\left(aux_{old} \left(\frac{g-1}{\sigma} - 1 \right) (\xi - 1) + \frac{g-1}{\sigma \left(\frac{g-1}{\sigma} - \frac{g-1-1}{dg} \right)^{(\alpha-1)(\epsilon-1)}} \right) (\epsilon - 1)}{f^\epsilon \left(f^{1-\epsilon} \left(aux_{old} \left(\frac{g-1}{\sigma} - 1 \right) (\xi - 1) + \frac{g-1}{\sigma \left(\frac{g-1}{\sigma} - \frac{g-1-1}{dg} \right)^{(\alpha-1)(\epsilon-1)}} \right) - 1 \right)} \hat{f}_t \\
& + \frac{f^{1-\epsilon} \left(\frac{g-1}{\sigma} - 1 \right) (\xi - 1)}{f^{1-\epsilon} \left(aux_{old} \left(\frac{g-1}{\sigma} - 1 \right) (\xi - 1) + \frac{g-1}{\sigma \left(\frac{g-1}{\sigma} - \frac{g-1-1}{dg} \right)^{(\alpha-1)(\epsilon-1)}} \right) - 1} \widehat{aux}_{oldtech,t-1} \quad (B30) \\
& + \frac{\xi \left(\frac{g-1}{\sigma} - 1 \right) \left(\frac{f^{1-\epsilon} \left(\frac{1}{\sigma \left(\frac{g-1}{\sigma} - \frac{g-1-1}{dg} \right)^{(\alpha-1)(\epsilon-1)}} - \frac{(\alpha-1)(\epsilon-1)(g-1) \left(\frac{1}{\sigma} - \frac{1}{\sigma dg} + \frac{g-1-1}{dg^2} \right)}{\sigma \left(\frac{g-1}{\sigma} - \frac{g-1-1}{dg} \right)^{(\alpha-1)(\epsilon-1)+1}} \right)}{\xi \left(\frac{g-1}{\sigma} - 1 \right)} - \frac{f^{1-\epsilon} (g-1)}{\sigma \left(\frac{g-1}{\sigma} - \frac{g-1-1}{dg} \right)^{(\alpha-1)(\epsilon-1)-1}} \right)}{\sigma \xi \left(\frac{g-1}{\sigma} - 1 \right)^2} \hat{g}_t \\
